Abstract- In this paper, the adaptive equalization techniques are used to transmit data through a communication channel. Because the signal can not be demodulate perfectly at the output of a communication system. However, in practically, all the channels are non ideal and noisy in nature. So, to recover the original signal after demodulation, equalizers minimize the error between the original transmitted signal and demodulated signal. In this paper Least Mean Square (LMS) and Constant Modulus Algorithm (CMA) Algorithms are used.

Keywords: Adaptive Filter, Adaptive Equalization, Channel Equalization, LMS Linear Equalization RLS Linear Equalization and Constant Modulus Algorithm.

I. INTRODUCTION

An adaptive equalizer is an equalizer that automatically adapts to time-varying properties of the communication channel. The main function of the adaptive channel equalization is to eliminate intersymbole interference (ISI) and the additive noise as much as possible in
a communication channel. Communication systems transmit a signal from one point to another across a communication channel, such as an electrical wire, a fiber optical cable, or a wireless channel. In this paper, adaptive equalizer system is an equalizer that automatically adapts to time-varying properties of the communication channel. The adaptive equalizer is used in high-speed communication systems, which do not use differential modulation schemes or frequency division multiplexing. It is frequently used with coherent modulations such as phase shift keying, mitigating the effects of multipath propagation and Doppler spreading.

So the adaptive equalizer compensates the signal distortion. During the transmission process, the signal that contains information might become distorted [1]. To compensate for this distortion, you can apply an adaptive filter to the communication channel. The adaptive filter works as an adaptive channel equalizer. The figure 1 shows the basic block diagram of an adaptive channel equalization system [6] & [7].

![Figure 1 basic block diagram of an adaptive channel equalization system](image)

In the figure 1, s (n) is the input signal that you transmit through the communication channel, and x (n) is the distorted output signal. To compensate for the signal distortion, the adaptive channel equalization system completes the following two modes.

**A. TRAINING MODE**

This mode helps us to determine the appropriate coefficients of the adaptive filter. When you transmit the signal s(n) to the communication channel, you also apply a delayed version of the same signal to the adaptive filter. In the previous figure, \( z^{-\Delta} \) is a delay function and d(n) is the delayed signal. y(n) is the output signal from the adaptive filter.
and $e(n)$ is the error signal between $d(n)$ and $y(n)$. The adaptive filter iteratively adjusts the coefficients to minimize $e(n)$. After the power of $e(n)$ converges, $y(n)$ is almost identical to $d(n)$, which means that you can use the resulting adaptive filter coefficients to compensate for the signal distortion [8].

**B. DECISION-DIRECTED MODE**

After determining the appropriate coefficients of the adaptive filter, we can switch the adaptive channel equalization system to decision-directed mode. In this mode, the adaptive channel equalization system decodes the signal $y(n)$ and produces a new signal $\hat{s}(n - \Delta)$, which is an estimation of the signal $s(n)$ except for a delay of $\Delta$ taps [8].

So the adaptive filters play a vital role in the channel equalization. The general set up of adaptive filtering environment is shown in Figure 2.

![Figure 2 General set up of Adaptive Filter](image)

Where $k$ is the iteration number, $x(k)$ denotes the input signal, $y(k)$ is the adaptive filter output, and $d(k)$ defines the desired signal. The error signal $e(k)$ is calculated as $d(k) - y(k)$. The error is then used to form a performance function or objective function that is required by the adaptation algorithm in order to determine the appropriate updating of the filter coefficients. The minimization of the objective function implies that the adaptive filter output signal is matching the desired signal in some sense [3].
II. ADAPTIVE EQUALIZATION TECHNIQUES

There are two types of equalizers which is used in the communication channel to compensate for signal distortion, one is the reference equalizer that uses the LMS algorithm and second is the configurable equalizer in which we use Least Mean Square (LMS), Normalized LMS, Variable Step-Size LMS, Recursive Least Squares (RLS), and Constant Modulus Algorithm (CMA).

A. LMS AND CMA EQUALIZER

The upper part of the figure 3 is LMS linear equalizer. The CMA equalizer simulation transmits a general QAM signal, modeling the channel using channel model. The equalizer receives the signal from the channel and, as training symbols, a subset of the modulator's output. The equalizer operates in training mode at the beginning of each frame and switches to decision-directed mode when it runs out of training symbols. And the same signal is transmitted via a CMA Equalizer. The example contrasts the signals before and after equalization to illustrate the effect of the equalizer which is shown in results.

IV. CONCLUSION

In this paper, the two types of adaptive equalizer for communication systems are reviewed. One is Least Mean Square (LMS) linear equalizer and second is Constant Modulus Algorithm Equalizer. The adaptive nature of the filter allows it to actively cancel out the adverse effects of the channel even without knowing the characteristics of the channel beforehand. This paper compares the LMS equalizer and Equalizer system.
